Lost IUD penetrating bladder wall

Thanks to Vural and colleagues who reported their interesting case of a misplaced intrauterine device (IUD).1 I would like to mention some points in their case:

With the increased uptake of intrauterine methods2 and the majority of uterine perforations said to occur at the time of device insertion (but go undetected), uterine perforation is more frequent than Vural et al.3 suggest.

Uterine perforation is now undiagnosed at the time of IUD insertion procedure, also because patients are asymptomatic despite this complication having occurred. There is currently greater use of analgesia prior to as well as local anaesthetic (including injectable) during IUD insertion procedures.

To facilitate early diagnosis of uterine perforation, especially in the absence of symptoms, clinicians should have a low threshold for performing, or referring for, pelvic ultrasonography. Instances of difficult insertion, insertion after difficult removal, where uterine sounding measurements are much different from the previous ones of a patient’s (which is usually a difficult removal of an old device), and no visible threads at routine follow up post-IUD insertion are examples.

Fortunately most services where IUD fitting procedures take place are not equipped with ultrasound scanners. Where there is local access to ultrasound or a referral has to be made, appointment waiting times tend to cause a delay in diagnosis of uterine perforation. Similarly, an appointment for laparoscopic removal of a misplaced device could be a few months away in an initial counselling on intrauterine methods4 to include information about the small risk of uterine perforation and its management will be helpful to patients interested in this highly effective method of contraception.

Two cases of broken Implanon®

We thought Journal readers might be interested to hear about two cases of broken Implanon® that we came across in our practice recently.

Between October 2003 and December 2009 we fitted 465 Implanon and removed 254. We have always reassured clients that the implant cannot break as it is very flexible, and we showed clients when we removed an implant how it could be bent and stretched without breaking. We cannot, however, state with certainty any more after having removed two broken implants within a 7-week period.

The first client, an 18-year-old, had only used condoms previously. She had an Implanon fitted on 20 May 2009. She was seen on 1 July 2009 as she was worried that the implant had broken. It was situated subdermally in her left inner upper arm over the triceps and we reassured her it felt intact but bent. She was otherwise happy with the implant. She came back to the clinic on 12 December 2009 as she had been advised to ask for the implant to be removed as she had been bleeding since the end of July with only 3 or 4 non-bleeding days. She declined a trial with contraceptive pills and stated she wanted to use condoms in the future, so we proceeded to remove her implant using the ‘pop-out’ technique. It was a successful, easy removal but we were really surprised when we saw the implant. It was nearly broken in half and was just the fine sheath. It had two further breaks and was also bent (Figure 1). On questioning, the client admitted that she often played with the implant.

The second client was 22 years old. She used condoms previously when one split and she became pregnant. Her implant was fitted after a termination of pregnancy in April 2007. She was happy with her implant initially but later she experienced irregular prolonged bleeding and so she was ‘topped up’ with the combined oral contraceptive pill, which controlled the bleeding as long as she took the pills regularly. The client was seen in clinic on 3 February 2010 after she had decided to have her implant removed and continue taking the combined pill. The implant was subdermally situated in her left inner upper arm over the triceps and felt intact. It was removed easily by means of the ‘pop-out’ technique. This implant was also broken into two halves (Figure 1) and once again the client agreed that she played with her implant a lot.

We have been experimenting with the implants we removed and feel that the only explanation could be a repetitive bending action that weakens the structure of the rod. We tried bending one of these implants around 200 times and only managed to bend it not break it.

We could find only one published article referring to another case of a broken Implanon.1 In this case and in our two cases there was irregular bleeding. As Pickard and Bacon suggested in their article, the broken implant could result in an inadequate release of the progesterone and thus be responsible for the irregular bleeding. These authors recommended that if a broken implant is suspected of causing irregular bleeding then it should be replaced.

We spoke with a doctor from the pharmaceutical company concerned and were unable to obtain any more information about similar cases; however, it seems that the hypothesis of Pickard and Bacon could be true. We could try to confirm this hypothesis by checking blood levels of etonogestrel, however this is an expensive test.
