Embracing post-fertilisation methods of family planning: a call to action

Elizabeth G Raymond, Francine Coeytaux, Kristina Gemzell-Danielsson, Kirsten Moore, James Trussell, Beverly Winikoff

ABSTRACT
Family planning methods that act when administered after fertilisation would have substantial benefits: they could be used longer after sex than current emergency contraceptives, and potentially a woman could use them only on relatively rare occasions when her menstrual period is delayed. Although such methods would displease abortion opponents, they would likely be welcomed by many women. Research to develop post-fertilisation fertility control agents should be pursued.

BACKGROUND
Family planning methods that act after fertilisation have considerable appeal. Compared to currently available contraceptives, which are all designed primarily to keep sperm and egg apart, drugs that would act during or after union of these gametes might offer notable advantages. If used postcoitally, such drugs would be effective later after sex than emergency contraceptives that work only if taken before ovulation, and therefore they could serve more women and provide more benefit at a population level. A woman could potentially use a post-fertilisation method on a planned schedule only once in each menstrual cycle, no matter how many prior coital acts she had had in that cycle. If the drug were effective when administered after implantation of an embryo, timing would be flexible, and she might even be able to limit its use on average to a few times a year when her menstrual period was late. Importantly, post-fertilisation methods would eliminate the conceptual and logistic challenge of needing to obtain and initiate contraception before having sex, which can be daunting for both women and men.

Technically, development of a pharmacetical regimen that reliably disrupts the pregnancy process after fertilisation, either before or after implantation or both, might be challenging. Progesterone receptor modulators such as mifepristone, given in adequate doses at certain times in the menstrual cycle, can inhibit endometrial implantation of a blastocyst. Mifepristone, particularly in combination with a prostaglandin, does have the well-established ability to terminate pregnancy when administered after implantation. However, its efficacy very early in gestation is unclear. Other compounds, in this class of drugs or in others, may offer more promise. Multidisciplinary research may be needed to define the best option, but given our rapidly increasing understanding of reproductive physiology, ultimate success seems likely.

POLITICAL ASPECTS
The real hurdle is politics. Both the UK and USA governments define pregnancy as beginning at implantation (US Code of Federal Regulations 45 CFR 46.202), implying that a method that acted after fertilisation but before implantation should not be considered abortifacient. However, not everyone is comfortable with this definition. Interrupting the course of pregnancy after implantation is abortion by any definition. In face of the vehement opposition to abortion among some individuals and institutions, development of a method that does not act exclusively before fertilisation would take fortitude.

But support for a post-fertilisation fertility control drug may be substantial. Abortion is legally available in the UK, the USA, Canada, most of Europe, India, China and many other countries with established pharmaceutical industries that are capable of developing and marketing a new drug product. Most of the British and North American public supports access to abortion, particularly in early pregnancy; indeed, in both England and Wales and in the USA, nearly
one-third of women will actually have abortions at some point in their lifetimes. A large body of international data now clearly indicates that abortion is safer the earlier it is performed and that increasing access to legal early medical abortion methods is associated with reduced morbidity and mortality. Research from diverse settings has found that many women view medical abortion methods, particularly when used at home, as more natural and more compatible with their religious or ethical views than clinic- or hospital-based surgical procedures. Menstrual regulation – evacuation of uterine contents after missed menses without confirmation of pregnancy – is considered acceptable in some communities where explicit abortion is prohibited. Twenty years ago, a multi-country survey specifically designed to investigate women’s feelings about a post-fertilisation contraceptive pill found remarkably high acceptance. We have no evidence that women have changed since then; it is the current political environment that needs refocusing.

FUTURE STRATEGIES
One strategy that we could implement immediately is to refrain from extolling pre-fertilisation mechanisms of action to justify the legitimacy of existing contraceptives. Such conduct implicitly stigmatises post-fertilisation mechanisms as illogic. This behaviour has been particularly pronounced recently in efforts to defend access to hormonal emergency contraception (EC), which has been relentlessly attacked as a supposed form of early abortion. In fact, considerable data now indicate that the most widely used EC regimen containing levonorgestrel acts primarily, and probably exclusively, by disrupting ovulation. Certainly legislators and policymakers need to understand this evidence in order to avoid bad decisions based on misinformation. But women do not use EC to disrupt ovulation or another physiological event; they use it to avoid having babies. Indeed, the essential value of this method lies precisely in the attributes it shares with abortion: it is an efficacious, extremely safe, easily administered, postcoital means for reducing the serious medical and personal risks associated with unintended pregnancy.

Furthermore, we should openly acknowledge that some of the most effective standard contraceptive methods probably act, at least in part, after fertilisation. Both copper-bearing and hormone-releasing intrauterine devices are more likely to prevent intrauterine than ectopic pregnancies, which suggests that these devices sometimes disrupt embryo attachment to the endometrium. The near-perfect efficacy of the copper-bearing device for EC also indicates a post-ovulation effect. Chronic use of most hormonal contraceptives causes profound histological and biochemical changes to the endometrium; these changes have been postulated to diminish receptivity to implantation in any cycles in which ovulation and subsequent fertilisation occur. Oral EC products containing mifepristone or the related compound ulipristal are more effective than the levonorgestrel regimen; as noted above, mifepristone, at least, can affect pregnancy development after ovulation. Even breastfeeding, which is widely used for contraception in the first 6 months postpartum, has been postulated to impair implantation by altering hormone levels in ovulatory cycles. Although the precise role of these post-fertilisation mechanisms is unknown, they should certainly be celebrated, because without them the methods would not provide as much benefit as they do.

THE WAY FORWARD
Most importantly, we should get to work! Nothing is as compelling as success: given the importance of fertility control to women, an effective, safe method that fills gaps in the array of existing contraceptives will undoubtedly attract support regardless of its mechanism. Scientists and advocates are ready; they just need funding. Despite the political climate, surely intrepid donors exist who will step up to the mark. To meet the challenges of our increasingly complicated world, women deserve all possible options for controlling and preserving their reproductive health and lives.

Develop after-sex contraceptive pill for routine use, urge researchers

Science and acceptability to women not the main issues; political opposition biggest hurdle

[Embracing post-fertilisation methods of family planning: a call to action doi 10.1136/jfprhc-2013-100702]

A contraceptive pill that could be routinely used after, rather than before, sex and fertilisation is probably scientifically feasible and would probably be welcomed by many women, say researchers in the Journal of Family Planning and Reproductive Health Care.

But the biggest hurdle impeding its development is likely to be political opposition, they suggest - despite the fact that some current contraceptive methods, such as intrauterine devices (IUDs), can sometimes prevent pregnancy even after fertilisation.

There would be many advantages to routine “post-fertilisation” contraception - as distinct from emergency contraception that has to be used within 72 hours - write the US and Swedish specialists in reproductive health, public health, and economics.

For one, this method could be used for far longer after sex than emergency contraception, so would serve a much wider number of women than are currently able to access emergency contraception and use it within the defined time window.

It would also be more convenient, offering the potential to be used just once in the monthly menstrual cycle, no matter how many times a woman had had sex before taking it, or even when a period had just been missed.

“Importantly, post-fertilisation methods would eliminate the conceptual and logistical challenge of needing to obtain and initiate contraception before having sex, which can be daunting for both women and men,” write the authors.

There would, of course, be technical hurdles to overcome, they acknowledge, as it’s not clear whether some currently available drugs that can disrupt pregnancy either before or after implantation would work as effectively if used in this way.

But there are other promising compounds and the pharmaceutical know-how to develop them, confirm the authors. “Multidisciplinary research may be needed to define the best option, but given our rapidly increasing understanding of reproductive physiology, ultimate success seems likely,” they say.

Political opposition is likely to pose a far greater challenge, they emphasise, as both the UK and US governments define the start of pregnancy as implantation of the fertilised egg, and interrupting this afterwards “is abortion by any definition,” they write.

But abortion is legal in many countries and widely accepted by the public worldwide. And international data point to the greater safety of legal abortion the earlier it is carried out, they point out.

“Research from diverse settings has found that many women view medical abortion methods, particularly when used at home, as more natural and more compatible with their religious or ethical views than clinic or hospital based surgical procedures,” they write.

Survey evidence suggests that women back the idea of post-fertilisation contraception; all that’s lacking are “intrepid” funders who would be willing to kick-start the research, say the authors.

“To meet the challenges of our increasingly complicated world, women deserve all possible options for controlling and preserving their reproductive health and lives,” they conclude.
In an accompanying podcast, lead author Elizabeth Raymond, senior medical associate at Gynuity Health Projects in New York, acknowledges the need to win over policy makers. Specialists working in family planning have their part to play, she suggests.

“We need to stop extolling pre-fertilisation contraception as a good thing, because it implies that something that works after fertilisation is bad. We have to stop doing that,” she says.

“[Post-fertilisation] contraception doesn’t have to be acceptable to every woman,” she adds. “No method is acceptable to every woman now.”
